Air BnB Texas Project by Wyatt Salinas

This Air BnB data was downloaded from kaggle: https://www.kaggle.com/PromptCloudHQ/airbnb-property-data-from-texas. I have in interest in real estate data and data mining, so this will code will be tailored towards my interests. Feel free to ask questions if you have any, I am more than happy to talk about it or explain any of this code. This is 100% the code of Wyatt Salinas and no one else.

In [1]:
```python
# Will be working from the pandas library. There will be some sections where numpy and statistics will be used.
import pandas as pd
import numpy as np
import statistics
from sklearn.linear_model import LinearRegression
import matplotlib.pyplot as plt
import statsmodels.api as sm
from sklearn.linear_model import LogisticRegression
```

In [2]:
```python
data = pd.read_csv('Airbnb_Texas_Rentals.csv')
```

Below is the head (first 5 data points) from the data frame that was created from the kaggle data. I will want to change some of the columns of data to analyze the data better.

In [3]:
```python
data.head()
```

Out[3]:

	Unnamed: 0	average_rate_per_night	bedrooms_count	city	date_of_listing	description	latitude	longitude	title

Prior to starting any analysis, we will want to look into our data and see if there are any big issues. The first issue I will look for is NaN values. Below, I will use some call-outs to find where there are NaN values in the data set.

In [4]:
```python
nan_df = data[data.isna().any(axis=1)]
display(nan_df.head())
```

	Unnamed: 0	average_rate_per_night	bedrooms_count	city	date_of_listing	description	latitude	longitude	title	
25	26	NaN	2	San Antonio	July 2014	2 bedroom 4 bed chalet/town-home sleeps 6-8 wi...	NaN	NaN	ChaletAzul 2RM/4BD 30day rent Avail	https://
103	104	NaN	1	Mexia	March 2017	Cozy cabin at Lake Mexia has nice lake views, ...	NaN	NaN	Cozy cabin with great lake views!	https://w
104	105	NaN	1	Fort Worth	September 2015	We are located in a quiet neighborhood. Cute h...	NaN	NaN	Room And A Pool 2	https://w
105	106	NaN	1	Galveston	September 2016	My place is close to the beach, family-friendl...	NaN	NaN	down to earth private room (share common areas)	https://w
167	168	NaN	1	Fredericksburg	February 2016	Casita on Creek is a little cottage located on...	NaN	NaN	Casita on Creek	https://w

There aren't many (4) data points that contain NaN values. These will still need to be dropped to ensure that we are able to use accurate data when working with our analysis.

In [5]:
```python
data = data.dropna()
```

In [6]:
```python
nan_df = data[data.isna().any(axis=1)]
display(nan_df.head())
```

Unnamed: 0	average_rate_per_night	bedrooms_count	city	date_of_listing	description	latitude	longitude	title	url

Above, there are no more data points in our data set that contain NaN as a value.

The next potential issue is the way our data is stored. We will want to make sure that we are using integers or float values for any mathematical analysis that will take place. Let's see what type of data we are working with...

In [7]:
```python
data.dtypes
```

Out[7]:
```
Unnamed: 0                  int64
average_rate_per_night     object
bedrooms_count             object
city                       object
date_of_listing            object
description                object
latitude                  float64
longitude                 float64
title                      object
url                        object
dtype: object
```

Average rate per night is an object and I will want this to be an integer without the $ symbol, so that this can be analyzed as a numerical value.

In [8]:
```python
data['average_rate_per_night'] = data['average_rate_per_night'].apply(lambda x: x.split('$')[1])
```

In [9]:
```python
data['average_rate_per_night'] = data['average_rate_per_night'].astype(int)
```

The average rate per night should now be an int32 instead of the object and we will want to make sure that the dollar sign is now eliminated.

In [10]:
```python
data.dtypes
```

Out[10]:
```
Unnamed: 0                  int64
average_rate_per_night      int32
bedrooms_count             object
city                       object
date_of_listing            object
description                object
latitude                  float64
longitude                 float64
title                      object
url                        object
dtype: object
```

In [11]:
```python
data.head()
```

Out[11]:

	Unnamed: 0	average_rate_per_night	bedrooms_count	city	date_of_listing	description	latitude	longitude	title

The dollar sign has been eliminated from the average rate per night and it is now an integer. We can begin working mathematically on this when needed.

Let's find the mean, min, and max prices of the average rate per night on our data. We can see if anything looks odd and if we need to look into it further.

In [12]:
```python
mean_price = data['average_rate_per_night'].mean()
max_price = data['average_rate_per_night'].max()
min_price = data['average_rate_per_night'].min()

print(f'The mean price of the data is {mean_price}')
print(f'The max price of the data is {max_price}')
print(f'The min price of the data is {min_price}')
```

```
The mean price of the data is 211.55975188011197
The max price of the data is 10000
The min price of the data is 10
```

10000 dollars a night and 10 dollars a night is probably unlikely, we can look further into this data. It is possible if it is a mansion or the other could likely be a shared studio...

In [13]:
```python
data.loc[data['average_rate_per_night'] == 10000]
```

Out[13]:

There are (4) different data points that have the average rate per night as 10000 dollars. They actually seem accurate as I see that each house has a good amount of bedrooms (>4), I see the keyword of mansion a couple of times, I see 11000 square feet, the word huge,etc...

I may look into this further in the future, but as of now I will keep them as is.

In [14]:
```python
data.loc[data['average_rate_per_night'] == 10]
```

I would like to change date_of_listing from it being merged together as an 'object' to it being split up and then extra columns will be added. There will be a 'Month' column as well as a 'year' column. We could potentially look into sorting by year and price and see if inflation or just cost of living is increasing.

In [18]:
```python
data['Month'] = data['date_of_listing'].apply(lambda x: x.split(' ')[0])
data['Year'] = data['date_of_listing'].apply(lambda x: x.split(' ')[1])
del data['date_of_listing']
del data['Unnamed: 0']
data.head()
```

Let's now find the average_rate_per_night for each city. We will first need to find the amount of cities that are in this data. If there are many cities, then I might end up filtering data where the city has to have at least a count of 5.

In [19]:
```python
data['city'].unique()
```

Out[19]:
```

Yes, there are very many cities. I will now use the groupby function to find the count of each city and take the top 10 based on the amount of listings for that given city...

In [20]:
```python
data_by_city = data.groupby('city').count()
data_by_city.rename(columns={"url":"City_Count"}, inplace=True)
data_by_city = data_by_city.drop(['average_rate_per_night', 'bedrooms_count','description','latitude', 'longitu
data_by_city.head()
```

Out[20]:

city	City_Count
Abilene	106
Addison	22
Alamo Heights	2
Alba	2
Aledo	5

In [21]:
```python
data_by_city = data_by_city.sort_values(['City_Count'], ascending = False).reset_index()
data_by_city.head(30)
```

Out[21]:

	city	City_Count
0	Houston	1501
1	Austin	1477
2	San Antonio	1223
3	Dallas	1144
4	Fort Worth	998
5	Corpus Christi	641
6	College Station	480
7	Irving	403
8	Bryan	358
9	New Braunfels	306
10	Galveston	304
11	McKinney	286
12	Arlington	272
13	Denton	252
14	Katy	216
15	South Padre Island	195
16	Port Aransas	187
17	Rockport	184
18	Horseshoe Bay	168
19	Richmond	157
20	Marble Falls	154
21	Plano	152
22	Conroe	151
23	League City	138
24	Canyon Lake	134
25	Wimberley	132
26	Lago Vista	131
27	Spicewood	126
28	Bandera	124
29	Spring	121

We could take the top 10 cities by using data_by_city[0:9], but I want to use as many unique functions as possible. So, I will use a more unique fuction below and will only take cities that have over 304 (not including 304) listings so that the last city will be New Braunfels.

In [22]:
```python
data_by_city = data_by_city[data_by_city['City_Count'] > 304]
data_by_city
```

Out[22]:

	city	City_Count
0	Houston	1501
1	Austin	1477
2	San Antonio	1223
3	Dallas	1144
4	Fort Worth	998
5	Corpus Christi	641
6	College Station	480
7	Irving	403
8	Bryan	358
9	New Braunfels	306

I will now use these cities on the orginal data to keep these cities and then get rid of the rest of the data. We are still looking for the average air bnb price of each city that is in the top 10 cities by the listing count.

In [23]:
```python
city_list = data_by_city['city'].tolist()
city_list
```

Out[23]:
```
['Houston',
 'Austin',
 'San Antonio',
 'Dallas',
 'Fort Worth',
 'Corpus Christi',
 'College Station',
 'Irving',
 'Bryan',
 'New Braunfels']
```

In [24]:
```python
top_cities_data = data[data['city'].isin(city_list)]
top_cities_data
```

7	Dallas	112.897727
8	San Antonio	93.530662
9	Irving	85.702233

It appears that New Braunfels has the highest average_rate_per_night and Irving has the lowest. Remember that each of these cities has over 300 listings, so there is a good amount of data to back up this claim of the average_rate_per_night in Texas.

Let's now look at the average price per night based on the year it was listed. My knowledge of economics would tell me that there should be an increase every year. The housing market tends to increase around 3 percent per year, so my hypothesis would be that the renting market will also increase by 3 percent per year. There are likely many factors that will prove me incorrect, but let's see first.

In [29]:

8	2016	210.976955	16.504190	8.486633
9	2017	287.917314	76.940358	36.468608

So, it appears that our finidings don't find an exact 3 percent increase per year. There are obviously many factors that are in play where it would be expected to not find a perfect 3 percent increase. Some factors could be: how many houses are available in the market, how many houses are listed at that time on air bnb, all houses for each year would stay exactly the same, all houses are availbe to be rented year-round and the pricing doesn't change (likely air bnb values fluctuate based on location and based on the time of year).

Price does appear to trend upward, we can use CUSUM to see if we can detect change... We can use our Dollar_Change column from the price_year_data dataframe from above to run this experiment.

x_t = observed value at time t
μ = mean of x, if no change

Detecting an increase

$$S_t = \max\{0, S_{t-1} + (x_t - \mu - C)\}$$

Is $S_t \geq T$?

St will be our value that we are tracking. This will change as we go through the data. C will be a number that we will come up with where we can control how quickly or slow change is detected. A large C will result in a slower detection, a smaller C will result in a quicker detection. T is our threshold. When the threshold is detected, we know that change is detected.

In [34]:
```
dollar_change
```

Out[34]:
```
[0,
 4.888888888888886,
 6.447245564892626,
 45.25920452926934,
 4.667489552618747,
 -18.39828670300028,
 14.99469570398756,
 7.613528320452303,
 16.504189567617487,
 76.94035810885418]
```

Because there is not that much data, it won't be the easiest to find a good C value or a good threshold value. But we can eye the data and see that change could be detected around 2011 as there was a 32% increase (45 dollar increase). We can first look at the data with no C to see how it looks.

In [35]:
```
C = 0
St = [0] * len(dollar_change)

dollar_change_mean = statistics.mean(dollar_change)

for i in range(1, len(dollar_change)):
    St[i] = max(0, St[i-1] + (dollar_change_mean - dollar_change[i] - C))

St.pop(-1)
St
```

Out[35]:
```
[0,
 11.0028424644692,
 20.44732825293466,
 0,
 11.224241800739339,
 45.5142598570977,
 46.41129550646822,
 54.689498539374,
 54.077040325114595]
```

The St increases quickly to 45 and then gradually ends up at 54. Let's try it now with a C value and a threshold value and see where the change is detected. We will use a c value of 12.9 (10% of the smallest value) and a threshold value of 10.

In [36]:
```
C = 12.9
t = 10

years = price_year_data['Year'].tolist()

St = [0] * len(dollar_change)

dollar_change_mean = statistics.mean(dollar_change)

for i in range(1, len(dollar_change)):
    St[i] = max(0, St[i-1] + (dollar_change_mean - dollar_change[i] - C))
    if St[i] > t:
        print(f'The year where change is detected is {years[i]}')
        print(f'The St value is {St[i]} while the detection threshold was {t}')
        break
```

```
The year where change is detected is 2013
The St value is 21.390018056358365 while the detection threshold was 10
```

let's try it with a larger C value and keep the same t value. There is such a large increase, that likely this won't matter. We will use a C value of 25 and the same t value of 20.

In [37]:
```
C = 20
t = 10

years = price_year_data['Year'].tolist()

St = [0] * len(dollar_change)

dollar_change_mean = statistics.mean(dollar_change)

for i in range(1, len(dollar_change)):
    St[i] = max(0, St[i-1] + (dollar_change_mean - dollar_change[i] - C))
    if St[i] > t:
        print(f'The year where change is detected is {years[i]}')
        print(f'The St value is {St[i]} while the detection threshold was {t}')
        break
```

```
The year where change is detected is 2013
The St value is 14.290018056358363 while the detection threshold was 10
```

We can see that the higher the c value the closer it was to that same threshold. This shows that as c gets larger, a larger the change will need to be to be detected. Here is the C value of 0 with the same threshold of 10.

In [38]:
```
C = 0
t = 10

years = price_year_data['Year'].tolist()

St = [0] * len(dollar_change)

dollar_change_mean = statistics.mean(dollar_change)

for i in range(1, len(dollar_change)):
    St[i] = max(0, St[i-1] + (dollar_change_mean - dollar_change[i] - C))
    if St[i] > t:
        print(f'The year where change is detected is {years[i]}')
        print(f'The St value is {St[i]} while the detection threshold was {t}')
        break
```

```
The year where change is detected is 2009
The St value is 11.0028424644692 while the detection threshold was 10
```

With no c value, change is detected immidiately. With a smaller c value, the more sensitive the detection will be.

All in all, we can likely say that there is noticeable change in 2013. With a c value of 20 and a threshold value of 10, it is detected. This is qutie a large c and a small threshold value relative to the data. We can also see that there is a 32 percent increase in price between 2012 and 2013, so it makes sense that we will detect a large change at that point.

Machine Learning to predict nightly stay price

I want to use the amount of bedrooms in all of the data to determine how the amount of rooms correlates to the average rate per night. I will use linear regression to graph the count of bedrooms (factor) vs. the average rate per night (response variable). I will then use an OLS (Ordinary Least Squares) summary to show the actual change in price per every one unit increase of a bedroom.

In [39]:
```
ml_data = data[['average_rate_per_night', 'bedrooms_count', 'city', 'Year', 'url']]
ml_data
```

Out[39]:

	average_rate_per_night	bedrooms_count	city	Year	url

18209 rows × 5 columns

Here are the unique values of bedroom count. There are (2) main issues that I see as of right now. One is that all of these values are 'str' type variables. The other is that the 'Studio' is one of the unique values. We will want to convert 'Studio' to some sort of numerical value so it is easier to interpret.

In [40]:
```
ml_data['bedrooms_count'].unique()
```

Out[40]:
```
array(['2', '4', '1', '3', 'Studio', '7', '5', '8', '6', '9', '11', '13',
       '10'], dtype=object)
```

I will assume Studios are the equivalent to half a bedroom. This makes the model a bit simpler and easier to explain, which can be very powerful. Studios can be assumed anything under 1 in my opinion, I will make it 0.5 as it is somewhere between 0 rooms and 1 rooms.

In [41]:
```
ml_data['bedrooms_count'] = ml_data['bedrooms_count'].replace('Studio', 0.5)
```

```
<ipython-input-41-04d42bed86d9>:1: SettingWithCopyWarning:
A value is trying to be set on a copy of a slice from a DataFrame.
Try using .loc[row_indexer,col_indexer] = value instead

See the caveats in the documentation: https://pandas.pydata.org/pandas-docs/stable/user_guide/indexing.html#ret
urning-a-view-versus-a-copy
  ml_data['bedrooms_count'] = ml_data['bedrooms_count'].replace('Studio', 0.5)
```

Converting all of the values to float values. This will allow us to run numerical analysis.

In [42]:
```
ml_data['bedrooms_count'] = ml_data['bedrooms_count'].astype(float)
```

```
<ipython-input-42-f68c6f2d5e44>:1: SettingWithCopyWarning:
A value is trying to be set on a copy of a slice from a DataFrame.
Try using .loc[row_indexer,col_indexer] = value instead

See the caveats in the documentation: https://pandas.pydata.org/pandas-docs/stable/user_guide/indexing.html#ret
urning-a-view-versus-a-copy
  ml_data['bedrooms_count'] = ml_data['bedrooms_count'].astype(float)
```

Below we are confirming that all of these values are floats before proceeding. These are all floats (because of the value and then the dot).

In [43]:
```
ml_data['bedrooms_count'].unique()
```

Out[43]:
```
array([ 2. ,  4. ,  1. ,  3. ,  0.5,  7. ,  5. ,  8. ,  6. ,  9. , 11. ,
       13. , 10. ])
```

x is the 1st column which is the count of the bedrooms. This has to go through a reshape so that it can be predicted (this is just a part of the LinearRegression() function). y is the 0th column, whihc is the average rate per night.

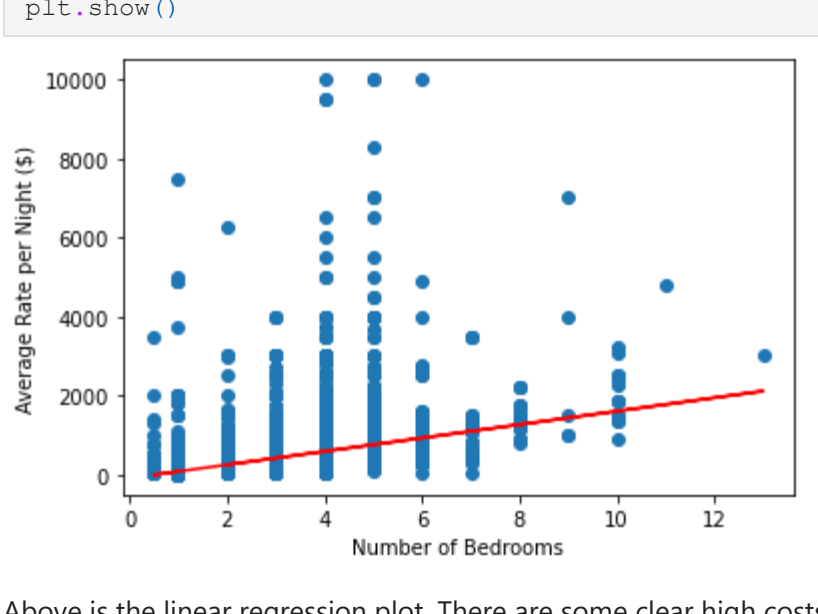
In [44]:
```
x = ml_data.iloc[:,1].values.reshape(-1,1)
y = ml_data.iloc[:,0].values.reshape(-1,1)
```

In [45]:
```
model = LinearRegression()
model.fit(x,y)
```

Out[45]:
```
LinearRegression()
```

In [46]:
```
y_predict = model.predict(x)
```

In [47]:
```
plt.scatter(x,y)
plt.plot(x, y_predict, color='red')
plt.xlabel('Number of Bedrooms')
plt.ylabel('Average Rate per Night ($)')
plt.show()
```



Above is the linear regression plot. There are some clear high costs per night that appear to skew the data. We can check the OLS next and see what results we get. We likely will lower the top average rate per night as some of these high values seem quite unrealstic (for the average individual).

In [48]:
```
result = sm.OLS(y,x).fit()
print(result.summary())
```

```

Notes:
[1] R² is computed without centering (uncentered) since the model does not contain a constant.
[2] Standard Errors assume that the covariance matrix of the errors is correctly specified.
```

Currently each extra bedroom will cost an extra 133.86 dollars.

Data looks quite skewed. For now, I will keep the price between 0-1500 dollars a night as that seems more reasonable. I will go ahead and run the same steps again to see what we get.

In [49]:
```
ml_data_new = ml_data[(ml_data['average_rate_per_night'] <= 1500)]
```

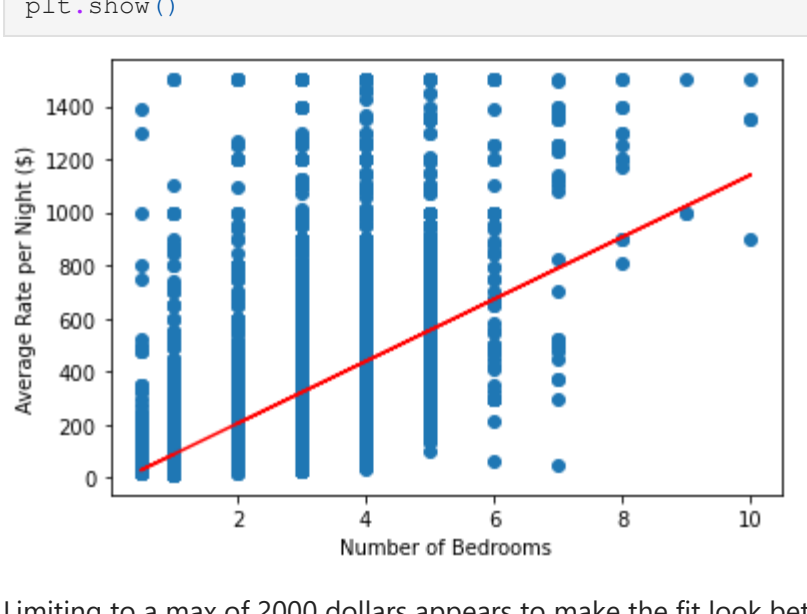
In [50]:
```
x = ml_data_new.iloc[:,1].values.reshape(-1,1)
y = ml_data_new.iloc[:,0].values.reshape(-1,1)
```

In [51]:
```
model = LinearRegression()
model.fit(x,y)
```

Out[51]:
```
LinearRegression()
```

In [52]:
```
y_predict = model.predict(x)
```

In [53]:
```
plt.scatter(x,y)
plt.plot(x, y_predict, color='red')
plt.xlabel('Number of Bedrooms')
plt.ylabel('Average Rate per Night ($)')
plt.show()
```



Limiting to a max of 2000 dollars appears to make the fit look better. We can see a deeper analysis when looking at the OLS summary below.

In [54]:
```
result = sm.OLS(y,x).fit()
print(result.summary())
```

```
                                 OLS Regression Results

```

Now, each extra bedroom will cost an extra 105.19 dollars. The R squared value is 0.668 which holds a fairly strong correlation. There is still a lot of data in this dataset that could be sorted through. We should likely look through each studio that appears to be > 400 dollars and understand why that is. We could similarly do this with each bedroom count and try to sort through the "bad" data or perhaps incorrect data. This could be a whole report on its own. I won't go through this now, but would want to if this data needs to be considered significant.

Machine Learning to Predict what a certain rental should cost

Let's say it is 2015 and a family is wanting to vacation to a certain city in Texas, wants a certain amount of rooms, and wants to keep it under a certain cost. This machine learning model will sort through the data in real time based on all of these factors.

Here are the factors... The family will be planning their vacation for 2016, they want to travel to San Antonio, 3 rooms, and they want to keep the cost per night under 250 dollars. Let's find a list of all of the houses for rent that are available.

In [55]:
```
input_year = '2016'
input_city = 'San Antonio'
input_rooms = 3
input_nightly_cost = 125
```

In [56]:
```
results = ml_data[(ml_data['bedrooms_count'] == input_rooms) & (ml_data['Year'] == input_year) & (ml_data['city
results = results.sort_values(['average_rate_per_night'], ascending=True).reset_index()
del results['index']

results
```

Out[56]:

From these reults, there are 25 different rental houses that have what the family is looking for. The average_rate_per_night is sorted from smallest to largest. If they are on a tight budget, they can look from the top to bottom by searching the url codes to see what they think of each house. This can be repeated until the get the desired house that is wanted for rent.

An interesting addition would be to find a way to add in the cleaning costs. I am not too sure how these costs are included, but it would be a good addition if it is based on a percentage of the total cost of the stay.

Let's do one more example and see what it would be like it if it were SuperBowl weekend in Houston in 2016 for 6 rooms and a max nightly cost of 5000 dollars.

In [57]:
```
input_year = '2016'
input_city = 'Houston'
input_rooms = 6
input_nightly_cost = 5000
```

In [59]:
```
results = ml_data[(ml_data['bedrooms_count'] == input_rooms) & (ml_data['Year'] == input_year) & (ml_data['city
results = results.sort_values(['average_rate_per_night'], ascending=True).reset_index()
del results['index']

print(f'Results for a {input_rooms} bedroom house in {input_year} in {input_city} for a max nightly cost of {ir
display(results)
```

```
Results for a 6 bedroom house in 2016 in Houston for a max nightly cost of 5000... There are a total of 2 house
s that match the criteria:
```

	average_rate_per_night	bedrooms_count	city	Year	url
0	1599	6.0	Houston	2016	https://www.airbnb.com/rooms/13369339?location...
1	4000	6.0	Houston	2016	https://www.airbnb.com/rooms/17016003?location...

This has been automated so now the individual will just have to input the desired values into the input variables above. The urls can be checked to see if these houses are adequate enough for what is desired.

This is the end of my analysis. As stated before, this is 100% my work and am open to talking further about this information.
